

Astroinformatics I (Semester 1 2024)

# Python Introduction

**Nina Hernitschek**

Centro de Astronomía CITEVA  
Universidad de Antofagasta

June 3, 2024

# Motivation

We have seen how to write shell commands.

Shell commands are efficient tools for working with files and directories, such as creating and deleting files, merging files, removing columns from tables...

Once we want to implement more **sophisticated analytical tools**, other programming languages such as **Python** are a better choice.

In many programming languages, so-called **libraries** maintain functions that accomplish such complex tasks. Python offers libraries for tasks such as plotting, astronomical calculations, statistics, machine learning... and much more.

Outlook

# Why use Python?

The **Python ecosystem** provides a single environment that is sufficient for the vast majority of astronomical analysis. It does so on several levels:

- open source, which means it is free (as opposed to proprietary languages (like IDL) which require you to buy a license)
- powerful language, many scientific libraries available.
- strong set of 3rd party analysis tools that are professionally and actively developed.
- robust methods for binding with C, C++ and FORTRAN libraries (speed, legacy)
- standard library support for web, GUI, databases, process management, etc.
- very active user and developer community

# Installing Python

## The Anaconda Repository

It features over 8,000 open-source data science and machine learning packages, built and compiled for all major operating systems and architectures.

<https://www.anaconda.com/>

# Installing Python

## Conda

Conda is an open-source package and environment management system for Windows, macOS, and Linux. Conda quickly installs, runs, and updates packages and their dependencies. It also easily creates, saves, loads, and switches between environments on your local computer. Despite created for Python programs, it can package and distribute software for any language.

```
[bash-3.2$ conda install pandas
Collecting package metadata (current_repodata.json) : done
Solving environment: done

## Package Plan ##

  environment location: /opt/anaconda3

  added / updated specs:
    - pandas

The following packages will be downloaded:

package           |      build          |
-----|-----|
pandas- 1.         | py39he9d5cce_1      | 9.4 MB
-----|-----|
Total:              |                      | 9.4 MB

The following packages will be UPDATED:
```

# Installing Python

Python can be used in a variety of ways: from the console (terminal), by loading program code previously written and saved in an editor, or as Jupyter notebooks.

We use Python 3.x. Python 2 is officially not supported as of January 1, 2020. In case you're still on Python 2.7, upgrade now as this course has a lot of code that won't run on Python 2.

# Interacting with Python

Within Python, you have access to two different terminals, the Python terminal and the iPython terminal (interactive Python).

To begin an interactive iPython session, simply type

```
$ ipython
```

You should see your prompt change to

```
[IN] :
```

with a line number. You are now in iPython.

To instead run a Python script, simply type

```
$ python3 my_script.py
```

Outlook

# Interacting with Python

```
print('hello world!')
```

## Definition

A print statement is a line of code which tells the interpreter (the program that turns your commands into computer bits and executes them) to output something to the screen.

In the above the phrase "hello world!" was placed inside quotation marks, and being surrounded by parenthesis.

Here, `print` is acting as a **function**, something that takes an argument and returns a result, similar to a mathematical function such as  $\sin(x)$ .

The quotes, on the other hand, are described in the next section - they are the `string` data type, and can be either single or double quoted.

# Data Types

Python, like most programming languages, uses **data types**.

While some data types are obvious, other data types seem more arbitrary at first glance: For example Python makes the distinction between integers (the counting numbers), and floats (numbers with decimals). It does so because of the way computer processors store information in bits, but it leads to the interesting (and important) characteristic that 42 and 42. are different in Python, and take up different amounts of computer memory.

# Data Types

Some **basic data types** are listed and defined below:

**Integers:** The counting numbers. Examples: -1, 0, 1, 2, 3, 4, 5, ...

**Floats:** Decimal numbers. Examples: 1., 2.345, 6.3, 999.99999, ...

**Strings:** An iterable data type most commonly used to hold words/phrases or path locations. Denoted by single or double quotes. Examples: "cat" ,  
"/home/username/directory", "1530", ...

**Boolean:** A data type with only two possible values: True, or False. They are used in conditional statements.

**Lists:** Stored lists of any combination of data types, denoted with brackets. Examples: [1,2,'star','fish'] or [1, 2, [3, 4, 5], 'star']  
(notice that you can have lists within lists)

**Numpy Arrays:** Like lists, but can only contain one data type at a time, and have different operations. Defined in `numpy`, not native Python, but so ubiquitous we include them here.

# Data Types

Python also allows for **composed data types** such as the ones below:

Tuples: Also like a list, but immutable (un-changable). These are defined with parentheses. Example: `tuple_1 = ('hi', 1, 4, 'bye')`

Dictionaries: A collection of pairs, where one is a *key* and the other is a *value*. One can access the value attached to a key by indexing the dictionary by key:  
`dictionary_name['key']`

# Data Structures

## Arrays vs. Lists

We begin with lists, as these are the native data type within Python. Let's define a list:

```
[IN]: my_list = [1,5,2,7,3,7,8]
```

Assume this list contains the rounded distances in parsecs of several nearby stars. We multiply by 2, as e.g. an equation has a factor of  $2d$ :

```
[IN]: my_list*2  
[OUT]: [1,5,2,7,3,7,8,1,5,2,7,3,7,8]
```

This obviously didn't work as intended: a new list with the original list repeated  $N$  times was created.

This default behavior this actually makes sense: recall that lists can contain any data type, and indeed any combination of data types. If our list contained a mix including strings or any other non-numerical data type, this operation would fail if defined this way.

# Data Structures

## Arrays vs. Lists

The correct way to multiply the list elements by a factor  $N$  is the following:  
We have to utilize what is known as **iterating** to go through the list one by one and replace each value with  $N$  times itself. Example:

```
[IN]: [i*2 for i in my_list]
[OUT]: [2,10,4,14,6,14,16]
```

As it turns out, there is a shorter way to apply mathematical operations to every element of a collection. Numpy arrays allow to perform mathematical operations on entire arrays all at once. Example:

```
[IN]: my_array = np.array([1,2,3])
[IN]: my_array*2
[OUT]: array([2,4,6])
```

This is also faster than iteration as arrays are being treated computationally as matrices, which can be computed very efficiently.

The procedure of extracting subsets of a larger array/list is known as **slicing**, or **indexing**.

By convention, this index starts with 0, rather than one (this is true for most programming languages). Here is a sample list, with the indices for each entry listed below:

```
list_1 = [1, 2, 3, 4, 'star', 198]
index:   0  1  2  3  4      5

By convention, this index starts with 0, rather than one (this is true for most programming languages). Here is a sample list, with the indices for each entry listed below:

```
list_1 = [1, 2, 3, 4, 'star', 198]
index:   0  1  2  3  4      5
```

We now extract the first entry of the array:

```
[IN]: list_1 = [1, 2, 3, 4, 'star', 198]
[IN]: x = list_1[0]
[IN]: print x
[OUT]: 1
```

# Array Manipulation

```
list_1 = [1, 2, 3, 4, 'star', 198]
```

```
index:    0  1  2  3  4      5
```

We can also extract the last entry (in a very convenient way):

```
[IN]: list_1 = [1, 2, 3, 4, 'star', 198]
[IN]: x = list_1[0]
[IN]: print x
[OUT]: 1
[IN]: y = list_1[-1]
[IN]: print y
[OUT]: 198
```

The same works for the second last entry, and so on.

# Dictionaries

The final primary data container data type in Python are dictionaries.

## Definition

A dictionary is a Python container, like a list or array, but which uses *keys* instead of indices to specify elements within the container. That is, the order of elements (values) in a dictionary is irrelevant, and values are retrieved by indexing for the appropriate key (which can be almost anything).

Most of the time we will write what is known as scripts, or programs.

## Definition

A program is a self-contained list of commands that are stored in a file that can be read by Python.

Essentially, it is a text file, with each line being the exact syntax you would have typed into the terminal.

Python then opens your program and runs it through the interpreter, line by line.

For example, if this is what you did in interpreter before:

```
[IN]: import numpy as np
[IN]: import matplotlib.pyplot as plt
[IN]: x = np.arange(100)
[IN]: y = x**2 + np.sin(3*x)
```

then you could write a program in a text file that looked like this:

```
import numpy as np
import matplotlib.pyplot as plt
x = np.arange(100)
y = x**2 + np.sin(3*x)
```

To start the program from the terminal:

```
$ python3 simple_program.py
```

# Control Flow Statements

So far, we have Python programs that are interpreted line by line in the order of their line number: sequential commands.

The real power of programming, however, lies in our ability to write programs that don't just contain a list of sequential commands but which execution depends on various inputs. This is done by **control flow statements**.

The control flow statements are similar to what we saw for `bash` scripts.

# Conditional Statements

The syntax of the if statement in Python is:

```
if condition:  
    # body of if statement
```

The if statement evaluates condition:

If condition is evaluated to True, the code inside the body of if is executed.

If condition is evaluated to False, the code inside the body of if is skipped.

## Condition is True

```
number = 10  
if number > 0:  
    # code  
  
# code after if
```

## Condition is False

```
number = -5  
if number > 0:  
    # code  
  
# code after if
```

# Conditional Statements

An if statement can have an optional **else** clause.  
The syntax of the if...else statement is:

```
if condition:
    # block of code if condition is True
else:
    # block of code if condition is False
```

The if...else statement evaluates the given condition:

If the condition evaluates to True,  
the code inside if is executed  
the code inside else is skipped

If the condition evaluates to False,  
the code inside else is executed  
the code inside if is skipped

Condition is True

```
number = 10
if number > 0:
    # code
else:
    # code
# code after if
```

Condition is False

```
number = -5
if number > 0:
    # code
else:
    # code
# code after if
```

# Conditional Statements

The `if...else` statement is used to execute a block of code among two alternatives.

However, if we need to make a choice between more than two alternatives, then we use the `if...elif...else` statement.

The syntax of the `if...elif...else` statement is:

```
if condition1:
    # code block 1
elif condition2:
    # code block 2
else:
    # code block 3
```

1st Condition is True

```
let number = 5
if number > 0 :
    # code
elif number < 0 :
    # code
else :
    # code
# code after if
```

2nd Condition is True

```
let number = -5
if number > 0 :
    # code
elif number < 0 :
    # code
else :
    # code
# code after if
```

All Conditions are False

```
let number = 0
if number > 0 :
    # code
elif number < 0 :
    # code
else :
    # code
# code after if
```

# Conditional Statements

We can also use an if statement inside of an if statement. This is known as a nested if statement.

The syntax of nested if statement is:

```
# outer if statement
if condition1:
    # statement(s)

    # inner if statement
    if condition2:
        # statement(s)
```

Notes:

- We can add else and elif statements to the inner if statement as required.
- We can also insert inner if statement inside the outer else or elif statements (if they exist).
- We can nest multiple layers of if statements.

Motivation

# Conditional Statements

An example:

```
#Example: A Simple Conditional  
x = 5  
y = 6  
  
if (2*x**2 > y**2):  
    print('condition holds')
```

The `if` keyword tells the interpreter to evaluate the truthiness of the rest of the line, up to the colon. In the case above, the `if`-statement would indeed print `condition holds`, because  $2 \times 5^2 = 50 > 36$ .

Like for functions, all lines to be considered part of the conditional must be indented.

# Loops

The two primary loops in Python are the `while` and `for` loops.

## Definition

A `while`-loop is repeats a specific block of code sequentially as long as a certain condition is met.

---

*#Example: A while-loop*

```
x = 100 # initialize x
while x > 5: #as long as x is greater than 5 run the indented code
    print x
    x = x -1
print('loop finished')
```

---

Eventually, after 95 times through the loop (and 95 prints), `x` would become `6-1=5`, which would no longer satisfy the `while` statement. The interpreter would then move on to the next line of code outside of the loop.

# Loops

## Definition

A `for`-loop is a set off block of code that contains a temporary variable known as an iterator, and runs the block of code over and over for different specified values of that iterator.

# Loops

## Definition

A for-loop is a set off block of code that contains a temporary variable known as an iterator, and runs the block of code over and over for different specified values of that iterator.

```
#Example: A for-loop  
arr = [1,2,3,4,5,6,7,8,9,10]  
for i in arr:  
    if i %2 ==0:  
        print i
```

The % sign means "modulo", and the conditional would read "if i divided by two has a remainder of 0" (the even numbers). The letter i is a generalized iterator: with `for i in arr` you are telling the computer to run the block of code, replacing i in the block with the first second, third, etc. element in the array. (You could use any character/combination of characters, but i is standard practice (followed by j, and k if necessary).

We have seen that there is a condition to end the loop, the **break condition** (also known as *test condition*). If we had not included the  $x = x-1$  part of the code,  $x$  would never end up being 5 or less.

For this it is important when using loops to **not forget the break condition**. Otherwise the loop will not end.

For this it is important when using loops to **not forget the break condition**. Otherwise the loop will not end.

In case a loop won't finish or will simply take too long and you decide to interrupt it:

Python interpreters have built-in keyboard shortcuts to interrupt a program. (Usually this is **Ctrl** + **C**).

# Loops

# Loops

Multiple loops can be **nested** in case of iterating over more than one value in your code. This often happens when dealing with two-dimensional arrays.

```
# Example: Iterating a 2D Array
for i in range(len(x)-1):
    for j in range(len(y)-1):
        if arr[i,j]<1500.:
            arr[i,j]=0
```

In the above example, *x* and *y* would be variables representing the coordinates in the array. This particular block of code would run through every combination of *i*, *j* reaching each element in the 2D array, and if the value at any given point was below the 1500 threshold, it would just set that element to be 0.

# List Comprehension

Loops and if statements are both **computationally expensive operations**, so look for ways to reduce the number you use to **speed up your code**.

**Use list comprehension** instead:

In general: List comprehension offers a shorter syntax when you want to create a new list based on the values of an existing list. List comprehensions can utilize conditional statement to modify existing list (or other tuples).

This becomes especially efficient when using `numpy` for list comprehension:

One of the main benefits of libraries such as `numpy` is that they are designed for efficiency in mathematical operations on arrays.

Thus: Do not use any other technique if you can use list comprehension.

# List Comprehension

For example, here is a code to list all the numbers between 1 and 1000 that is the multiplier of 3:

```
L = []  
for i in range (1, 1000):  
    if i%3 == 0:  
        L.append(i)
```

Using list comprehension, it would be:

```
L = [i for i in range (1, 1000) if i%3 == 0]
```

The list L will be populated by the items in range from 0-1000 if the item's value is divisible by 3.

List comprehension works faster than using the append method.

# Loops

We can also replace the code from above for iterating a 2D array:

```
# Example: Iterating a 2D Array
for i in range(len(x)-1):
    for j in range(len(y)-1):
        if arr[i,j]<1500.:
            arr[i,j]=0
```

Using list comprehension with a where statement, we get:

```
array_name[np.where(array_name < 1500)[0]] = 0
```

# List Comprehension

## Key Points to Remember about List Comprehension

- List comprehension is an elegant way to define and create lists based on existing lists.
- List comprehension is generally more compact and faster than normal functions and loops for creating list.
- However, we should avoid writing very long list comprehensions in one line to ensure that code is user-friendly.
- Remember, every list comprehension can be rewritten in a `for` loop, but not every `for` loop can be rewritten in the form of list comprehension.

# Data Input/Output

A file is a container in computer storage devices used for storing data.

When we want to read from or write to a file, we need to open it first.

When we are done, it needs to be closed so that the resources that are tied with the file are freed.

Hence, in Python, a **file operation** takes place in the following order:

- Open a file
- Read or write (perform operation)
- Close the file

Outlook

# Data Input/Output

To open a file for reading, we use:

```
file1 = open('filename.txt','r')
```

where 'r' indicates we plan to write to the file.

A final close statement above tells Python to save and close the file.

When we are done with performing operations on the file, we need to properly close the file to free up the resources that were tied with the file.

```
#Example: Reading from a File  
# open a file  
file1 = open('test.txt', 'r')  
  
# read the file  
read_content = file1.read()  
print(read_content)  
  
# close the file  
file1.close()
```

# Data Input/Output

In a similar way we can **write** to files.

There are two things we need to remember while writing to a file.

- If we try to open a file that doesn't exist, a new file is created.
- If a file already exists, its content is erased, and new content is written.

In order to write into a file in Python, we need to open it in write mode by passing 'w' inside open() as a second argument.

Suppose, we don't have a file named test2.txt. Let's see what happens if we write contents to that file.

```
#Example: Writing to a File  
  
with open(test2.txt', 'w') as file2:  
    # write contents to the test2.txt file  
    file2.write('This is a test file.')  
    fil2.write('Added second line.')
```

## Different modes to open a file in Python

mode	description
<code>r</code>	Open a file for reading. (default)
<code>w</code>	Open a file for writing. Creates a new file if it does not exist or truncates the file if it exists.
<code>x</code>	Open a file for exclusive creation. If the file already exists, the operation fails.
<code>a</code>	Open a file for appending at the end of the file without truncating it. Creates a new file if it does not exist.
<code>t</code>	Open in text mode. (default)
<code>b</code>	Open in binary mode.
<code>+</code>	Open a file for updating (reading and writing)

# Data Input/Output

So far, we were ignoring issues like columns of varying length and possible improper values. A better option in such cases is provided by `numpy` as the function `np.genfromtxt`.

What `genfromtxt` does is the following: Internally it runs two main loops. The first loop converts each line of the file in a sequence of strings. The second loop converts each string to the appropriate data type. This mechanism is slower than a single loop, but gives more flexibility. In particular, `genfromtxt` is able to take missing data into account.

# Data Input/Output

As example, suppose we have the following text file called `my_data.txt`:

```
1 2 3 4
5 6 7 8
```

We import this file, while assigning different types to different columns:

```
#Example: Importing a file with numpy

import numpy as np

a = np.genfromtxt("my_data.txt",
dtype=[np.int, 32 int, np.float, 32 float])
print(a)
```

With now knowing about control flow statements and data I/O, you are now well equipped to put all of this together to write more complex code for data exploration.

We will also see how **libraries** can assist us with data exploration by providing sophisticated algorithms.
